ABSTRACT

Lactic acid bacteria (LABs) are a unique group of microorganisms found in the diet of nearly all humans and form an integral part of the healthy human microbiome. Some LAB strains exhibit a remarkable ability for autoaggregation, mediated by Snowflake Forming Collagen Binding Aggregation Factors (SFCBAFs)—a fascinating group of proteins described so far only in LABs. To date, only five SFCBAFs have been characterized in detail: AggL from *Lactococcus lactis*, AggE from *Enterococcus faecium*, AggLb from *Lacticaseibacillus paracasei*, AggLr from *Lactococcus raffinolactis*, and AggA from *Tetragenococcus halophilus*. In this study, we present bioinformatically predicted novel SFCBAF candidates and demonstrate their widespread distribution among LAB species. Furthermore, we provide evidence that such proteins may not be exclusive to LABs, as homologous sequences were also identified in phylogenetically distant bacteria such as *Staphylococcus aureus*, *Oceanobacillus* spp., *Bacillus* spp., and others, expanding our understanding of this unique protein family.

1. Introduction

Lactic acid bacteria (LAB) represent a unique group of microorganisms that are found in foods, such as meat products (*Carneiro et al.*, 2024), consumed by nearly every human on the planet and are also present in the microbiome of healthy individuals. In nature, LAB are not limited to food products—they can also be found in soil, on plants, and on or within both terrestrial and marine organisms. Thus, this group of bacteria is truly ubiquitous and is represented across nearly all ecological niches (*Akpoghelie et al*., 2025).

One of the remarkable properties of certain LAB strains is autoaggregation, ability to adhere among themselves or to other strains, forming visible aggregates *(Trunk, S. Khalil, & C. Leo*, 2018). There is substantial evidence suggesting that aggregation is closely linked to biofilm formation, adhesion, colonization, and host physiological functions *(Burgain et al., 2014; Du et al.*, 2022; *Kragh et al*., 2016; *Miljkovic et al*., 2015).

Among wide range of different aggregation factors, there is a distinct group that is referred to as Snowflake Forming Collagen Binding Aggregation Factors (SFCBAFs). These are large proteins that contain adhesion domains in the first part of the protein, followed by an immunoglobulin-like domain and then repeats domains. They are exported from the cell to the surface and subsequently

covalently anchored to the cell wall through a well-characterized mechanism involving the LPXTG cell wall anchor domain (*Siegel, Reardon, & Ton-That*, 2017). While the aggregation mechanism is still under investigation, it is believed that the adhesive properties are conferred by collagen-binding and immunoglobulin-like domains, whereas the repeat regions serve to spatially project the protein away from the cell surface (*Miljkovic et al*., 2016). At present, only five representatives of this group have been well characterized: AggL from *Lactococcus lactis*, AggE from *Enterococcus faecium*, AggLb from *Lacticaseibacillus paracasei*, AggLr from *Lactococcus raffinolactis*, and AggA from *Tetragenococcus halophilus (Endo et al., 2023; Kojic et al., 2011; Miljkovic et al., 2018, 2015; Veljović et al., 2017)*. In this study, we predict the presence of novel proteins from this group and perform their analysis.

2. Materials and methods

2.1. Selection of representatives for phylogenetic tree construction

To retrieve protein sequences for analysis, we used the local alignment tool BLASTP 2.16.0. Searches were conducted against NCBI databases using amino acid sequences of known SFCBAFs as queries. (*Sayers et al*., 2022). The presence of signal peptides in the retrieved proteins was predicted using SignalP 6.0 (*Teufel et al.*, 2022). Duplicate sequences were removed prior to further analysis.

2.2. Multiple sequence alignment and phylogenetic tree construction

Multiple sequence alignment of the protein sequences was performed using Clustal Omega, which employs hidden Markov models (HMMs) for improved accuracy (*Madeira et al*., 2024). The resulting phylogenetic tree was saved in Newick format (*Junier & Zdobnov*, 2010) and used for downstream clustering analysis.

2.3. Clustering of the phylogenetic tree

To assess diversity and select representatives from distinct evolutionary lineages, we calculated pairwise evolutionary distances between all taxa based on the phylogenetic tree generated by Clustal Omega. Using the resulting distance matrix, we applied KMeans clustering (Steinley, 2006), specifying ten clusters. From each cluster, we selected the most distant taxon from the cluster centre, i.e., the taxon showing the greatest divergence from the cluster's average profile. This approach allowed us to compile a set of phylogenetically diverse representatives for further analysis.

2.4. Domain structure analysis

To analyse the domain architecture of the proteins corresponding to the selected taxa, we used the online tool InterPro (*Paysan-Lafosse et al.*, 2023).

3. Results and discussion

3.1. Phylogenetic analysis of potential SFCBAF representatives

In order to assess the distribution of aggregation factors, we performed BLASTP 2.16.0 searches using sequences of previously described SFCBAF-type factors (AggL, AggE, AggLb, AggLr, and AggA) against the NCBI protein database (Sayers et al., 2022). All predicted protein sequences were subsequently screened for the presence of signal peptides required for protein cell export using SignalP 6.0, and sequences lacking a signal peptide were excluded. The remaining candidates were then analysed for the presence of LPxTG anchor motifs, taking into account known motif variants as described previously (*Malik et al.*, 2023) and our internally obtained data. As a result, we assembled a dataset of 246 proteins, including the previously described ones, each of which had less than 100% sequence identity to any other in the set. A phylogenetic tree was constructed based on Clustal Omega alignment (results shown in Supplementary). During our research we identified novel SFCBAF-like factors in non-LAB bacteria, including *Mycoplasma sp. P36-A1*, *Oceanobacillus* spp., *Virgibacillus* spp., *Gracilibacillus* spp., *Jeotgalicoccus halotolerans*, *Aliicoccus persicus*, *Pseudogracilibacillus* spp., *Ornithinibacillus* sp., *Bacillus* spp., *Amphibacillus* sp., *Atopostipes* spp., *Irregularibacter muris*, *Eubacterium nodatum*, *Corticicoccus populi*, *Coprococcus* spp., *Staphylococcus agnetis*, *Staphylococcus aureus*, *Mammaliicoccus stepanovicii*, and *Lentibacillus sp. JNUCC-1*. Interestingly, aside from *Mycoplasma sp. P36-A1*, all other bacteria were Gram-positive, which may indirectly suggest a conserved mechanism of cell surface anchoring for these proteins.

3.2. Domain structure analysis of potential SFCBAF representatives

To understand the diversity of newly predicted SFCBAF representatives, we clustered the phylogenetic tree into 10 groups based on pairwise distances between its leaves and selected one most "central" representative from each cluster. In addition, we included the longest (5511 amino acids) and the shortest (1063 amino acids) SFCBAF representatives. We also re-verified the presence of leader and anchor sequences. The list of the selected representatives is provided in Table 1.

We aligned the selected representatives once again relative to each other (Figure 1, A) and performed domain structure analysis using InterPro (Figure 1, B). All potential representatives showed a similar structural organisation to previously described SFCBAF-type proteins: following the leader peptide, all contained adhesion domains (InterPro ID: IPR008966) with collagen-binding regions. The bacterial adhesion domain consists of a β-sandwich formed by 9 β-strands arranged in 2 layers with a Greek-key topology, representing a subclass of the immunoglobulin-like fold. Such domains are commonly found in surface-associated proteins and are essential for bacterial adhesion to host cell surfaces (*Symersky et al*., 1997). The number of adhesion domains varied from 1 (in the longest protein) to 7 (in several representatives). These domains are followed by an immunoglobulin (Ig)-like domain (InterPro ID: IPR013783) characterized by a prealbumin-like fold. Ig-like domains are among the most widely distributed protein modules found in diverse organisms. They frequently mediate interactions, often through β-sheet pairing with other Ig-like domains. Ig-like folds are present not only in immunoglobulins but also in a variety of other proteins, including T-cell antigen receptors, cell adhesion molecules, MHC class I and II antigens, muscle proteins such as titin, and others*(Bork et al., 1994; Halaby et al.*, 1999; *Potapov et al.*, 2004; *Teichmann & Chothia*, 2000). We hypothesize that adhesion domains, together with Ig-like domain, are crucial for aggregation. After the Ig-like domain, two organizational variants are observed: in one group, the Ig-like domain is repeated 6 to 19 times (excluding the first domain); in the other group, the repeats consist of a Cna protein B-type domain (InterPro ID: IPR008454). This domain has been well-characterized in the Cna protein of *Staphylococcus aureus*. Most probably if forms an extended stalk structure that positions the ligand-binding domain away from the bacterial surface. Cna is a collagen-binding MSCRAMM (Microbial Surface Component Recognizing Adhesive Matrix Molecules) and is necessary for *S. aureus* cells to bind to cartilage (*Foster & Höök*, 1998; *Shimoji et al*., 2003). The number of such repeats among the selected representatives ranges from 3 to 50. Finally, only one SFCBAF representative, *Enterococcus faecium* WP_002335623.1, displays a hybrid structure: after the initial Ig-like domain, there is another Ig-like domain followed by six Cna protein B-type domains. At the C-terminus of each protein, an LPxTG anchor motif is present, although in some cases, it deviates from the canonical form. For example, in *Lactobacillus paracasei* WP_211757376.1 and *L. paracasei* BGNJ1-64 AggLb, it is represented as MPNTG, while in *E. faecium* WP_002335623.1, it appears as LPTKE.

4. Conclusion

Lactic acid bacteria represent a unique group of microorganisms closely associated with the food industry, making them of particular interest for research. The aggregation of lactic acid bacteria gives them a distinctive phenotype and new properties, including potential adhesion to the human gastrointestinal tract and the displacement of other pathogenic microorganisms. In this study, we demonstrated the prevalence of SFCBAF-type aggregation factors. Investigating such bacteria may help improve the properties of LAB used in the food industry, including in the meat industry.
